Results from second midline

preliminary and incomplete version – please do not cite

Abstract

It is often observed that smallholder farmers sell most of their marketable surplus immediately after the harvest when seasonal price movements reach their lowest point, instead of waiting just a few more months until prices recover. Most explanations for this apparently sub-optimal behavior focus on economic or infrastructural issues, such as credit constraints or lack of storage facilities. In this study, we zoom in on two potential behavioral explanations. One explanation is situated at the household expenditure side, and assumes that households face challenges in accurately predicting future expenditures, systematically underestimating future needs. A second potential explanation is situated at the household income side. Here the assumption is that farmers suffer self-control problems and are not sophisticated about this leading them to sell too early and/or at lower prices. To test these hypotheses, we conduct two planning based interventions among a sample of Malawian smallholder farmers: a detailed expense budget and a sales plan with explicit commitment to timing of sales, quantities and prices. At the second midline, we find that households that were exposed to the sales plan are more likely to have sold and less likely to have bought between October and December when prices are high.

Keywords: smallholder marketing, cash crops, budget neglect, commitment failure.

1 Introduction

It is often observed that smallholder farmers sell most of their marketable surplus or cash crops immediately after the harvest to itinerant traders at the farm gate. Selling immediately after the harvest is not optimal: Thin and poorly integrated markets often mean that immediately post harvest prices in excess supply areas drop to their seasonal low. In addition to high supply immediately post harvest, agricultural commodities are often not yet in optimal condition. For instance, in the case of maize, fresh grains are generally not dry enough, requiring further processing and leading to increased risk of rot by the trader. Often, this is used by buyers as an additional reason to further drive down the price paid to the farmer.

Over time, prices gradually recover, reaching their seasonal high just before the next harvest. At this time, many farmers have run out of stock, and need to turn to the market to buy back maize at prices that are often a multiple of what they received, a phenomenon known as the “sell low-buy high” puzzle (Stephens and Barrett, 2011; Burke, Bergquist, and Miguel, 2018). Van Campenhout, Lecoutere, and D’Exelle (2015) further show how farmers loose out twice, as transaction costs are passed on by traders to farmers when traders buy commodities from farmers in rural areas to aggregate in consumer centers, but farmers also incur transaction costs when they buy back (often from the same traders in towns, or large warehouses in trading centers).

The literature suggest many possible reasons why farmers choose the sell early at low prices instead of waiting a few months until prices recover. Farmers may simply not have the space and infrastructure available to safely store large quantities of maize for extended periods of time (Omotilewa et al., 2018). They may be in urgent need of cash after the lean season (Burke, Bergquist, and Miguel, 2018; Dillon, 2021). Price movements may be unpredictable and farmers may be too risk averse to engage in intertemporal arbitrage (Cardell and Michelson, 2020). It may be that traders only visit villages immediately after harvest, and farmers do not have the means to transport maize to markets themselves. Furthermore, issues related to social taxation may mean farmers convert maize to cash, which is easier to hide from friends and family (Jakiela and Ozier, 2015).

Most of the explanations above focus on neoclassical constraints to farmers’ exploiting inter-temporal arbitrage. In this study, we zoom in on two potential behavioral explanations why farmers seemingly sell at sub-optimal timing. One potential explanation is situated at the household expenditure side, and assumes that households face challenges in accurately predicting future expenditures. Such budget neglect leads farmer to sell more early on and save too little for later in the year (Augenblick et al., 2021). A second potential explanation is situated at the household income side. Here the assumption is that farmers face self-control issues and are unsophisticated about this (Duflo, Kremer, and Robinson, 2011). As a result, farmers end up selling at lower prices and earlier in the year than they would if they would be able to better commit (Ashraf, Karlan, and Yin, 2006).

The above hypotheses are tested with a field experiment among smallholder farmers in Malawi. These farmers produce (a mix of) maize, groundnuts and soybean from which at least part is destined for the market. Our experiment takes the form of a simple parallel design with two treatment arms and one control group. A first treatment arm tests for the role of budget neglect in explaining the sell low-buy high paradox: Farmers that are randomly assigned to the first treatment arm are taken through a detailed budgeting exercise immediately after harvest. In particular, in this intervention a trained enumerator sits with the household head and fills in a budget matrix of projected expenses for each month in the coming year. The second treatment arm tests the importance of failure to commit. Farmers that are randomly allocated to the second treatment arm receive a sales planning intervention. Here, a trained enumerator sits with the household head and plans how much they plan to sell of which crop in which month during in the coming year. For each planned sale, the household head is also asked to commit to a minimum price is that they expect. Impact of the interventions on a variety of outcomes is compared against outcomes of a control group that did not get any intervention.

This document has been compiled immediately after the second midline survey was collected (via telephone). It is based on the [pre-analysis plan](#) and the [mock report](#), and is the follow-up of a similar document that documents [impact at the first midline survey](#) that was conducted 6 months post intervention. The report compares outcomes of households in the treatment groups to outcomes of households in the control group. We find that, consistent with the theory, the sales plan intervention leads farmers to sell more and buy less. The effect is particularly strong for maize, which is the primary crop for farmers in the region. We also find that budget planning increases joint decision making between husband and wife.

In the next section, we provide a selective overview of related studies. We then outline the main research hypothesis we want to test, and describe the interventions we will use to do so. We then turn to the data with subsections that present descriptives for the study population and balance between treatment and control groups. We then turn to the midline data and report attrition and impact on primary and secondary outcomes. A last section concludes.

2 Related Research

Why do farmers “sell low and buy high”? One of the most obvious neo-classical explanations is related to credit constraints. Using observational data, [Stephens and Barrett \(2011\)](#) find that to meet consumption needs later in the year, many farmers end up buying back grain from the market a few months after selling it, in effect using the maize market as a high-interest lender of last resort. [Burke, Bergquist, and Miguel \(2018\)](#) show that in a field experiment in Kenya, credit market imperfections limit farmers’ abilities to move grain intertemporally. Providing timely access to credit allows farmers to buy at lower prices and sell at higher prices, increasing farm revenues and generating a return on investment of

almost 30%. [Dillon \(2021\)](#) uses the fact that in Malawi, primary school began 3 months earlier in 2010 than in 2009, and notes that this prompted households with children to sell maize when prices are particularly low. To identify the impacts of liquidity constraints during the lean season, [Fink, Jack, and Masiye \(2020\)](#) offered subsidized loans in randomly selected villages in rural Zambia. They find that relaxing liquidity constraints not only changed marketing behavior, but also increased labor allocated to agricultural production (as opposed to day laboring as a coping strategy) and conclude that liquidity constraints thus contribute to inequality in rural economies in the longer run as well. While credit constraints thus seems to be an important reason why farmers sell immediately post harvest at low prices, we feel this is not the entire story. If farmers need urgent cash, it would make more sense to only sell part of the harvest to cover most urgent expenses, or to sell commodities that are less affected by price seasonality, like small livestock. However, farmers often seem to sell all of their marketable surplus immediately post harvest in a single transaction.

Risk averse farmers may also fail to delay sales if there is considerable uncertainty about the price in the future. A recent article by [Cardell and Michelson \(2020\)](#) argues that the “sell low buy high” puzzle is not a puzzle at all. Using 20 years of data from 787 markets in 26 countries, they argue that in many cases the price increase seems insufficient and too uncertain for farmers to engage in inter-temporal arbitrage ([Cardell and Michelson, 2020](#)). However, their analysis use prices obtained from market centers, which may be a poor proxy for the farm gate prices that farmers face: prices in main markets are generally much better integrated in the wider national, regional and even global economy, and so will be less prone to the extreme spikes and slumps that smallholder farmers in more remote areas experience.

A third reason may be that farmers have nowhere to safely store crops, so they just sell. This could be a lack of space, as the average smallholder often harvest 20-40 bags of 50kg of maize. But there are also risks related to pests and diseases affecting the stored maize. If lack of safe storage is the main reason why farmers do not engage in intertemporal arbitrage, then providing storage technology should delay sales. [Omotilewa et al. \(2018\)](#) indeed find that households that received PICS bags, a type of hermetically sealed bag of two layers of polyethylene liners and a third layer made from woven polypropylene, stored maize for a longer period and reported a substantial drop in storage losses. Again, we feel storage is indeed part of the reason, but it does not explain everything. For instance, this explanation is at odds with the fact that Agricultural Commodities Exchange (ACE) in Malawi consistently fails to fill its warehouses.

Another reason may be related to social taxation. If a farmer has a lot of maize stored in his house, this is visible for family and neighbors, and it will be very hard to deny if neighbors come and ask for help during the hunger season. Therefore, farmers may choose to convert their harvest to money, which is easier to hide, even though this comes at a cost. Social taxation has been found important in a similar marketing decisions where household seem to forgo the benefits of buying in bulk ([Dillon, De Weerd, and O’Donoghue, 2020](#)).

Related research on the more behavioral and psychological front that helps explain the puzzle is ongoing. [Augenblick et al. \(2021\)](#) study recurrent seasonal hunger in Zambia, which could be a direct consequence of suboptimal marketing behaviour, and conjecture that individuals tend to overestimate their available resources and consequently under-save. They test this hypothesis through an intervention that induces individuals to think through their budget set and formulate a spending plan. They find that treated households enter the hunger season with one additional month of savings, leading to a smoother spending profile over the year.

Our research is also related to an established literature on lack of self-control in cases where individuals have to make complex intertemporal decisions involving uncertain future events. If farmers are impatient and unsophisticated about this, nudges may be effective in reducing discretionary spending in increase investment in the future ([Duflo, Kremer, and Robinson, 2011](#)). [Dupas and Robinson \(2013\)](#) find that devices which simply help individuals harness the power of mental accounting helps them to save more.

3 Behavioural constraints to intertemporal arbitrage: Hypotheses and Interventions

The first potential behavioral explanation for the sell low buy high puzzle is situated at the household expenditure side, and assumes that households face challenges in accurately predicting future expenditures. In particular, we assume that farmers systematically underestimate how much money they need in the future and as a result sell too much immediately after the harvest. For example, immediately after harvest, they may budget for fresh seed from the agro-input dealer and for fertilizer, but they may forget that they also need pesticides and insecticides. Furthermore, farmers may underestimate the likelihood of, or simply forget to account for, unexpected events such illness within the family.

There are various reasons why individuals may suffer from this kind of budget neglect. In general, predicting the full set of expenditures under all possible states of the world is likely to be beyond the cognitive capacity of human beings ([Augenblick et al., 2021](#)). It is also related to the planning fallacy, where individuals typically underestimate the time it takes to complete a task, despite extensive experience with failure to complete the same task in a similar time frame in the past ([Buehler, Griffin, and Peetz, 2010](#)). Part of it may also be related to optimism bias if farmers neglect or underestimate the risk that adverse effects will happen to them ([Sharot, 2011](#)).

To test the first hypothesis, we designed an intervention that takes the farmer through a detailed budgeting exercise. In particular, the main decision maker within the household was provided with a template that needed to be filled in as detailed as possible. Pre-populated expenditure categories included education expenditures (school fees, uniforms,...), agricultural investment expenditures (seed, fertilizer,...), investment expenditure in non-agricultural businesses (retail

shop inventories,...), health and medical expenses (medicines, preventive doctor visit,...), household recurrent expenditure (food, utilities,...), household equipment and maintenance (furniture, renovation,...), and other expenditures (loan repayment, ceremonies,...). For each of these expenditure item lines, farmers were then asked to provide an estimate of the total cost for each month between May 2022 and April 2023 and write it down in the appropriate cell of the expenditure matrix. Farmers were also encouraged to provide their top 3 unexpected expenditures likely to occur between May 2022 and April 2023. We then calculate totals per month and also a grand total for the entire year. This first intervention will be referred to as treatment one (T1).

The second hypothesis is also related to cognitive limitations when planning, but this time at the income side of the farm household. While farmers may initially have a good idea of when to sell and at what price, various factor may lead them to revise the plans and sell sooner and at lower prices. These include unexpected events but also social taxation ([Jakiela and Ozier, 2015](#)) Furthermore, farmers may be influenced by various decision heuristics (such as seeing their neighbor sell their crop) that are at odds with their plans and again revise to sell earlier or at lower prices.

To test if the sell low-buy high puzzle is predominantly cause by a failure to commit, we develop, together with the farmer, a detailed sales plan for the year which is assumed to function as a commitment device closely modeled in the idea of mental accounting. Again using a template, we start by asking the farmer about the expected marketable surplus for maize, groundnuts and soybean. We then ask for each month between May 2022 and April 2023 how much the farmer is planning to sell for each of the crops, and what the minimum price and point in time should be before they sell. Also for the sales plan, we calculate totals per month and also a grand total for the entire year. This second intervention will be referred to as treatment two (T2).

We did not merely ask farmers to create these plans, but also encouraged them to hang them in a central place in the house or store them in a convenient location. We also encouraged them to update them regularly. Furthermore, to increase the likelihood that farmers use the plan, we also refer to the plan during midline surveys, and reiterate the importance of using these plans.

4 Data collection

Baseline data collection took place around the end of May and beginning of June 2022. Using tablet computers and Open Data Kit software, 31 enumerators interviewed 3534 farmers that were sampled from four districts in the Central and Northern Regions of Malawi (Kasungu, Ntchisi, Dowa and Mchinji). The study areas are characterized by rain-fed agriculture with a single agricultural season.

We selected farmers that produce maize, groundnuts and/or soybean. Maize is planted early in the year and harvest starts usually starts in April and proceeds through May. Soybean is harvested somewhat earlier, groundnuts somewhat

Figure 1: map of study area with sampled villages

later. Soybean and groundnuts can be sold pretty much immediately after the harvest; maize needs to be dried first.

To get a nationally representative sampling frame of the smallholder farmer population in Malawi, we rely on the list created by the Ministry of Agriculture for their Agricultural Input Programme (AIP). The AIP targets smallholder farmers in the villages who mostly registered with the village chiefs. We used a two-stage sampling procedure where we first sampled villages with the likelihood of a village being selected proportionate to the number of people that live in this village (such that larger villages are more likely to end up in the sample). We then randomly sampled 31 households in each of the sampled villages. Figure 1 gives a sense of coverage and dispersion of the interviewed households.

The focus of the study is on market participation and so the targeted study population consists of farmers that are likely to engage with markets. As such, we included qualifier questions in our survey, where we asked farmers if they were planning to sell maize, soybean or groundnuts during the 2022 season. Restricting our study population to a particular sub-population has implications for the interpretation of the results. For instance, we will see later that we find relatively high proportions of households reporting to sell to the market. As such, the particular nature of the study population, semi-subsistence smallholder farmers, needs to be kept in mind when interpreting results, as they may be

different from for example predominantly self-sufficient farmers.

Midline data was collected by phone over the course of one month (September 2022). A second midline was collected also by phone and took about three weeks (in January 2023). Results report here are from the second midline.

4.1 Farmer characteristics

Table 1 presents a number of summary statistics of sampled households and their heads at baseline. Eighty percent of households are headed by men. The average household is headed by a 43 year old with six years of schooling (primary level). The typical household has five members, living in houses of three rooms. Four in every 10 households have their main houses roofed with corrugated iron sheets (as opposed to thatch roofing). We find that the average distance of the households to the nearest all weather road and nearest market is 1 and 4 km respectively.

We also collected information on access to transport facilities or assets (either through ownership or hire). Results in Table 1 show that households mostly have access to a bicycle (72% of respondents) and ox-carts (60% of the respondents). Ox-carts are particularly important for transportation of harvest from the farms to the market. We also collected information on livestock asset ownership, as these are often a form of savings that can be used as a buffer stock to insulate consumption from income fluctuations.

Other household characteristics that affect market participation included access to credit, access to storage, membership of cooperatives, and whether farmers had already promised part of the 2022 harvest to a buyer. Table 2 shows that among the surveyed farmers, about 40 percent indicate that they have access to credit, and that less than a quarter had outstanding debts averaging MWK. 57,000 to repay after harvest. With regards to access to storage, 60 percent of the households reported that they have access, of which half indicated that the storage was crop specific. We also find that, while farmer participation in cooperatives is limited, a moderate share (40%) have access to storage space provided by the cooperative. Lastly, we look at the proportion of farmers that commit a part of their crop to buyers before harvest—a scenario that may often lead farmers to sell at unfavorable prices, or reduces the amount of harvest that farmers can sell after harvest. We find that only a negligible share of farmers (8%) had already promised (part of) the 2022 crop to buyers prior to harvest.

4.2 Baseline balance

We follow our pre-analysis plan and test baseline balance by constructing a standard balance table consisting of the following variables household/demographic characteristics (inspired by balance tables in [Duflo, Kremer, and Robinson \(2011\)](#); [Karlan et al. \(2014\)](#)): household head is female (1=yes), household size (number of people), age of household head (years), number of years of education of the household head (years), material of roof (corrugated iron = 1), number of rooms in the house, cultivated acreage (maize+groundnuts+soybean),

Table 1: Household characteristics

	Mean	Std dev	N
<i>Household head</i>			
Household head is male (1=yes)	0.791	0.407	3,534
Age of household head (years)	43.426	14.831	3,414
Schooling of household head (years)	6.329	3.489	3,427
Roof of main building is grass thatch (1=yes)	0.609	0.488	3,534
<i>Household characteristics</i>			
Roof of main building is corrugated iron (1=yes)	0.39	0.488	3,534
Household size (number of people)	5.043	1.992	3,530
Number of rooms in the house	3.202	1.178	3,534
Distance (kms) to nearest all weather road	1.308	3.433	3,346
Distance (kms) to nearest market	4.107	4.78	3,243
<i>Transport</i>			
Household has access to bicycle (1=yes)	0.719	0.45	3,534
Household has access to saloon car (1=yes)	0.218	0.413	3,534
Household has access to pick-up or lorry access (1=yes)	0.221	0.415	3,534
Household has access to ox-cart (1=yes)	0.595	0.491	3,534
Household owns a motorbike (1=yes)	0.11	0.313	3,534
<i>Livestock assets</i>			
Number of bulls/oxen/steers owned by household	0.123	0.653	3,533
Number of cows or heifers owned by household	0.128	0.799	3,532
Number of calves owned by household	0.053	0.495	3,533
Number of pigs owned by household	0.708	1.943	3,534
Number of goats owned by household	1.241	2.569	3,533
Number of sheep owned by household	0.055	0.519	3,531
Number of chicken owned by household	4.743	6.509	3,532
Number of ducks owned by household	0.282	1.501	3,533

Table 2: Household characteristics that affect market participation

	Mean	Std dev	N
<i>Credit</i>			
Do you have access to credit? (1=yes)	0.383	0.486	3,532
Do you have debts (cash or in-kind) to be repaid after harvest? (1=yes)	0.236	0.425	3,532
Estimated amount (Malawian Kwacha) of debt	56,878	92,788	819
<i>Storage</i>			
Do you have access to storage? (1=yes)	0.599	0.49	3,532
Is the storage crop specific? (1=yes)	0.482	0.5	2,114
<i>Cooperation</i>			
Are you member of a Cooperatives? (1=yes)	0.134	0.34	3,532

Is this Cooperative certified by the Agriculture Commodity Exchange? (1=yes)	0.727	0.446	472
<i>Advance selling</i>			
Did you already promise part of the 2022 harvest to a buyer? (1=yes)	0.077	0.267	3,532

whether the household hired in agricultural labour (1=yes), distance to nearest all weather road (km), and distance to nearest market (km). We report t-tests comparing treatment and control (unadjusted for multiple hypothesis testing) as well as a joint F-test from a regression of the treatment assignment on all variables in the balance table. Results are summarized in Table 3.

We find significant imbalance on some of the variables, particularly for the sales plan treatment (T2). While joint F-test for separate treatment control comparisons are not significant, we do find signs of imbalance when we use a likelihood ratio test derived from a multinomial model where the left hand side has three levels (T1, T2, Ctrl).

The pre-analysis plan also states that we assess balance on a range of characteristics that we will use to investigate heterogeneous treatment effects. The variables mentioned there are access to credit, access to storage facility, membership of (marketing related) cooperative, livestock asset ownership, and whether the household already makes a budget. Results for these variables are in Table 4.

5 Impact at midline

5.1 Attrition

As data collection for the September midline was by phone, we expected that we would not be able to reach some farmers, even though at baseline we always collected information on alternative ways to reach the farmers (for instance through village headship). From the original 3534 farmers that were interviewed at baseline, we successfully reached 3282 farmers, leading to an attrition rate of just over 7 percent. Enumerators made on average 12 attempts before indicating the farmers could not be reached. Treatments are not correlated to the likelihood that farmers are missing from the data (χ^2 test of independence of proportions is rejected at $p=0.248$).

5.2 Primary outcomes

We start with the most parsimonious specification by reporting simple difference between treatment and control farmers obtained from an Ordinary Least Squares regression that regresses the outcome of interest on two dummy variables indicating if the household received T1 or T2 respectively. Results are in the top panel of Table 5. In the bottom panel of Table 5 we show results after including additional controls. These include the outcome at baseline, baseline variables for which we found imbalance in Table 3, and village fixed effects. We start with Table 5, which reports results for maize; Tables 6 and 7 are similar tables but for groundnuts and soybean, respectively.

A first primary outcome we consider is stocks held of the commodity at the time of the midline survey. In particular, we asked farmers how many bags of the commodity (standard 50 kg bags) they have in store. As the distributions

are skewed to the right and includes zeros as well, we use an inverse hyperbolic sine transformation (Bellemare and Wichman, 2020). For both treatments, we expect a positive effect. Similar to Augenblick et al. (2021), we expect that when making households aware about future needs, they will reduce discretionary expenditures and save more for the future. Furthermore, if farmers expect prices to go up over time and this is reflected in their sales plan, farmers that are encouraged to commit to this sales plan will also be more likely to have saved more early on in the season.

We see that the average control farmer has about 1.383 bags of maize in store at the time of the survey. While we do find stocks are somewhat larger in the sample of farmers that were taken through a budgeting exercise, the difference is not significant. We similarly find that stocks are higher among farmers that made a sales plan. Farmers that were asked to commit to a sales plan have stocks that are about 5.8 percent higher than maize stocks of farmers in the control group, but also here the difference is not significant. If we add controls to the regression, the effect reduces substantially.

A second primary outcome tests if the household sold any of the crop in the interval between the intervention and the midline survey. Contrary to the what we expected earlier in the season at the first midline survey, we now expect that farmers that were treated would be more likely to sell. We find that 23.7 percent of households in the control group indicated that they made at least one sales transaction between now and the first midline survey. While we do not find an effect for the budgeting intervention, we do see that farmers that were

exposed to the sales plan treatment are more likely to have sold in the previous three months.

The third primary outcome is related to the second and is the quantity that was sold during the period between the intervention and the first midline survey. In addition to testing if farmers are more likely to sell after treatment, we also wonder if farmer sell more. We find that farmers in the control group sell on average 1.56 bags of maize. While the quantities sold are also higher, especially for T2, differences are not significant.

For farmers that did engage in sales, we can calculate the average price that farmers received for their crop. The aim of the intervention is to increase the price at which farmers sell. The farmers that sold in the control group got on average 342.992 MKW per kilogram of maize. While prices are again somewhat higher, and again particularly for T2, the differences are not significant.

We also consider behaviour related to purchases of the commodities as key primary outcomes. We expect that, especially later in the season, due to our interventions households will have to buy back less. We see that in the control group, of the farmers that already sold maize, about 70 percent also made at least one purchase of maize in the last three months. This is substantially higher than what we found in the previous survey round, when only 17 percent reported to have bought maize. As expected, we do see that the treatment reduced this share, again particularly for the sales plan treatment. As for sales, we also look at quantities bought and prices at which the commodities were bought. We find that for maize, the average control group household bought two and a half bags on average. We see that T2 farmers also bought significantly smaller quantities.

In Table 6, we repeat the entire analysis, but now for groundnuts. Households in the control group remain with virtually stocks. During the first midline we found that T2 farmers still had significantly higher stocks, which is consistent with the significantly higher likelihood of having sold in the previous three months for this treatment group. There are no effects on quantities sold, nor on prices received.

As for maize, we also asked if farmers had already bought groundnuts in the last three months. About 13 percent of farmers report buy back behaviour. Interestingly, we find that farmers in the T1 treatment group were more likely to have bought groundnuts. Finally, we do not find an impact on prices at which groundnuts were purchased, but as very few farmers bought groundnuts, sample size becomes too small to obtain reliable estimates.

Finally, Table 7 shows impact of the interventions on primary outcomes for soybean. As for maize, we see strong effects from the sales plan treatment: treated farmers are more likely to have sold at least once in the last three months, and on average also sold more. Furthermore, the T2 group also still have larger stocks of soybean. However, contrary to maize, there are no effects on buying behaviour.

5.3 Secondary outcomes

In this section, we look at some additional outcome which may be indirectly affected by the interventions. These outcomes may help explain some of the effect on primary outcomes, or they may be outcomes for which the expected effects are ambiguous. We again present separate tables for maize (Table 8), for groundnuts (Table 9) and for soybean (Table 10).

A first outcome we look at is the price in the near future. In particular, we asked all households what they expected the price would be around the end of February/beginning of March 2023. Table 8 shows that farmers still expect a sizable price increase: while we saw in the previous section that the average farmer in the control group only got about 340 MKW per kilogram of maize during the first few months after harvest, the price is expected to increase to about 500 MKW per kilogram a few months from now.

We also wonder if our intervention would affect intra-household dynamics, in particular who is in charge of sales of the commodity. We see that in about 56 percent of households, the decisions related to the sales of maize is taken by the male and female co-head jointly, with both co-head having equal voice. We find that this percentage is slightly higher among farmers that were exposed to the budgeting intervention.

Another secondary outcome we consider is related to who was sold to. In particular, we test if, in response to our interventions, farmers increase the likelihood that they sell directly to the market, as this is often the place where they can get the best price for their crop [Fafchamps and Hill \(2005\)](#). We find that few farmers in our sample sell maize directly to the market, and that there are no difference between the different treatment groups.

Finally, we asked farmers that sold between the harvest and the midline survey what the proceeds from the transaction was used for. We examine the effect of our interventions on two categories. One expenditure type, payment of school fees, is likely to be predictable by the farmer. A second expenditure type, health related expenses, is probably less predictable. We do not find that the treatment intervention changed the propensity that sales of maize were made for any of these expenses.

Turning to Table 9 for secondary outcomes of groundnuts, we see that farmers in the control group expect a further 25 percent increase of the price by the end of February/beginning of March 2023.

We further find that decisions related to the sales of groundnuts are made jointly in slightly less households than was the case for maize. While, similar to the maize case, the prevalence of joint decision making is somewhat higher in the T1 group, the difference is not significant. Groundnuts are rarely sold directly to the market, and there is also no effect of T1, nor T2. For the expense categories, we also find no significant effects.

Finally, Table 10 shows results for secondary outcomes for soybean. Control group farmers estimate that prices will be about 30 percent higher than what they were during the September-December period. Farmers report joint sales similar to groundnuts sales. The full models shows that as for maize, T1 in-

creases cooperation between spouses. There are no effects on other soy related outcomes.

Conclusion

In this paper, we test two behavioral explanations for the “sell low-buy high” puzzle. The first explanation assumes that farmers underestimate how much money they will need later on in the season, leading them to sell too much immediately post harvest at prices that are too low. We test this explanation through an intervention in which households are asked to prepare a detailed budget of what they will need for the entire year. It is expected that by making future expenditure more explicit, farmers will suffer less from budget neglect when making market participation decisions.

The second explanation assumes that farmers face challenges in planning and committing on the income side. For a variety of reasons such as temptation,

emergencies or social pressures, farmers are assumed to sell earlier than they would like to, and at lower prices than they envisioned. We test this using a light touch intervention where we ask farmers to prepare a detailed sales plan, indicating how much of each crop will be sold when during the coming year, and what the minimum price is they want for it, and hope this serves as a commitment device for the farmer.

We implement our field experiment in a sample of about 3500 farmers in four districts in the Central and Northern Regions of Malawi. Treatments were administered during baseline data collection immediately after the maize harvest in April 2022. Results in this paper are based on a second (telephone based) midline survey, which was done in January 2023.

We find evidence that households that were exposed to the sales plan treatment generally sell more later in the season than farmers in the control group. For maize, we also see that farmers in this treatment group are less likely to buy. This suggests that a sales plan is indeed an effective tool to reduce sell-low buy-high behaviour among smallholder maize farmers in Malawi. The budget intervention seems less effective in addressing sell-low buy-high behaviour. However, we find some evidence that budgets increase intra-household decision making related to sales.
